Chemiluminescence, or chemical light, is the principle behind the glow sticks or light sticks used as quick tools to grab when the electricity goes out. But they can also be used to diagnose diseases by identifying concentrations of biological samples. A new mechanism developed by Tel Aviv University researchers produces a 3,000-times-brighter, water-resistant chemiluminescent probe with particular application to medical and cancer diagnosis.

The research found that tweaking the electronic structure of current probes improves their inherent fluorescence. This could lead to the invention of a new single-component system with multiple applications including the detection and measurement of cellular activity that points to certain pathologies, such as cancer.

The research, conducted in collaboration with Dr. Christoph Bauer of Geneva University, repairs an energy-loss "glitch" in current chemiluminescent probes. Most systems use a mixture of one emitter molecule that detects the species of interest, and another two additional ingredients a fluorophore and a soap-like substance called a surfactant that amplify the signal to detectable levels. But energy is lost in the transfer process from the emitter molecule to the fluorophore, and surfactants are not biocompatible.

By adding two key atoms, a much brighter probe has been created than those currently on the market. In addition, this particular molecule is suitable for direct use in cells. Based on this molecule, the researchers developed sensors to detect several biologically relevant chemicals. They also used the chemiluminescent molecule to measure the activity of several enzymes and to image cells by microscopy.

The research was funded in part by the Israel Science Foundation, the Binational Science Foundation, the German Israeli Foundation, and the Israeli National Nanotechnology Initiative.
